

# Poor Little Children: The Socioeconomic Gap in Parental Responses to School Disadvantage\*

Inés Berniell<sup>†</sup>      Ricardo Estrada<sup>‡</sup>

February, 2019

## Abstract

This paper studies how parents react to a widely-used school policy that puts some children at a learning disadvantage: age at school entry. In specific, we analyze Spanish data on parental investment and find that college-educated parents increase their time investment and choose better schools when their children are the youngest at school, while non-college educated parents do not. Consistent with the increase in parental investment, we document a lower month of birth penalty among children with college-educated parents.

Keywords: parental investment, age at school entry, education inequality, compensating behaviour.

JEL Classification: I20, D10

# 1 Introduction

Life (policy) can put some children at a disadvantage. If this is the case, parents can react to disadvantage by changing their investment in their children and, potentially, mitigate it. However, parental reactions might depend on parental resources, with important implications for inequality and social mobility and for policy impacts. Our understanding of such responses is limited, however, because a proper empirical analysis requires both exogenous variation in exposure to disadvantage and the availability of detailed data on parental investment.

In this paper, we get around these limitations by looking at a variation in exposure to school disadvantage that is both well documented as potentially exogenous and easy to observe across datasets, including those with information on parental investment. In specific, we use time-use surveys and school-based questionnaires to study how parents from different socioeconomic statuses (SES) react to a widely-used school policy that puts some children at a learning disadvantage: the age at school entry.

Most countries dictate that children born during a given one-year period should start school at the same time. This (up to one-year) difference in the age of students in the same classroom can be reflected in performance. For instance, younger children might be less ready to acquire knowledge and, overall, to deal with the experience of formal schooling. If initial outcomes shape future outcomes, the age at school entry can have long-term consequences for schooling and labour market trajectories (see Subsection 2.1).

A large body of literature shows that starting school at an earlier age is indeed related to worse student performance, labour market outcomes, and criminal behaviour.<sup>1</sup> Furthermore, this negative effect might be greater among people from a disadvantaged background, at least in some contexts (see [Attar and Cohen-Zada, 2017](#) on Israel, [Grätz and Bernardi, 2017](#) on England, [Fredriksson and Öckert, 2014](#) on Sweden and [McEwan and Shapiro, 2008](#) on Chile).<sup>2</sup>

Before looking at potential differences in parental investments, we first document that younger children tend to perform worse in school than older children in Spain. Using data from four waves of the PISA survey, we find that students who started school at a younger age are more likely to have repeated a grade and to have lower test scores in mathematics and reading at age 15 than their older peers. For example, students born in December (the youngest in their cohort) are 10 percentage points more likely to have

---

<sup>1</sup>For student outcomes, see for example: [Bedard and Dhuey, 2006](#) and [Elder and Lubotsky, 2009](#) on the United States; [Mühlenweg and Puhani, 2010](#) on Germany; [Grenet, 2011](#) on France. For the effect on the probability of ADHD diagnoses: [Schwandt and Wuppermann, 2016](#); [Elder, 2010](#). For criminal behaviour: [Cook and Kang \(2016\)](#) and [Landersø, Nielsen, and Simonsen, 2016](#) on the United States and Denmark, respectively. For labour market outcomes: [Fredriksson and Öckert, 2014](#) on Sweden; [Bedard and Dhuey, 2012](#) and [Dhuey and Lipscomb, 2008](#) on the United States; and [Black et al., 2011](#) on Norway. The latter document that this age effect on earnings dilutes when people reach 30 in Norway.

<sup>2</sup>[Elder and Lubotsky \(2009\)](#), in contrast, find opposite results in the United States.

repeated a grade at age 15 than those born in January (the oldest).<sup>3</sup> We go further and explore how this pattern translates into long-term outcomes, using information from the Spanish population census. We find that adults who were younger at school entry have less schooling and less educated partners.

A causal interpretation of the documented age effect requires that 1) parents do not manipulate their child’s effective age of school entry (by postponing enrollment for one year); and 2) there is no connection between the characteristics of newborns and their month of birth. Some parents might be willing to enroll their children in school later than regular entry if they are sufficiently concerned about the negative effects associated with the age at school entry.<sup>4</sup> Spain enforces a strict birthday cut-off for school entry, so, even if they wish to, parents cannot opt for strategy 1) (see Section 2.2). Alternatively, there could be a connection between the characteristics of newborns and the month of birth if parental characteristics or relevant environmental (institutional) conditions that shape fetal (newborn) health vary during the year.<sup>5</sup>

We analyze the birth certificates from the universe of newborns in Spain from 2007 to 2014 to study potential seasonality in births.<sup>6</sup> Using census-type data allows us to detect birth patterns that could go unnoticed in survey data because of a small sample size. We find that there is indeed some seasonality in births. However, and this is key for a causal interpretation, we do not find significant differences in the characteristics of babies born in December and January (just before and after the birthday cut-off for entry to school, which is January 1st). We confirm this pattern by looking at differences in parental characteristics between people born in December and January, in the datasets used in our main analysis.

We, therefore, focus our analysis on people born in January (the oldest at school entry) and December (the youngest).<sup>7</sup> Using data from PISA, we show that the effect of the age of school entry is significantly larger among children from disadvantaged families. For instance, young students from low-SES families are 12.7 percentage points more likely to have repeated a grade at age 15 than older students from the same socioeconomic background. This gap is only 4 percentage points among students from high-SES families.<sup>8</sup>

To analyse whether this difference is related to parental investment according to family background, we assemble two different datasets with detailed information about parental

---

<sup>3</sup>This pattern echoes the findings of [Calsamiglia and Loviglio \(2016\)](#) on Catalonia.

<sup>4</sup>[Dhuey, Figlio, Karbownik, and Roth, 2017](#) document that postponing school enrollment is a common practice in the United States.

<sup>5</sup>Along these lines, [Buckles and Hungerman \(2013\)](#) documents seasonality in maternal characteristics in the United States.

<sup>6</sup>2007 is the first year in which parental characteristics are available in the birth certificate data.

<sup>7</sup>Across datasets, we focus our basic specification on people born in January and December of the same calendar year. However, when data is available, we compare individuals born in adjacent January and December months and find similar results (available in Online Appendix).

<sup>8</sup>This result is robust to using both binary and continuous specifications of the SES index.

investment: the two waves of the Spanish Time Use Survey (2003 and 2009, STUS) and the General Diagnostic Assessment (a national evaluation of 4th grade students undertaken in 2009, GDA, which has information about parental involvement and school characteristics).<sup>9</sup> Our focus on parental time investment in child development is grounded in the literature which shows that parental time input is important for the cognitive development of their children, particularly when they are young (Del Boca, Flinn, and Wiswall, 2014). We find that college-educated parents increase the amount of time they spend helping their children with school activities and that they choose schools with better inputs when their children are the youngest at school entry, while parents without a college education do not. Specifically, we find that college-educated parents spend on average five more minutes per day helping their children with school activities when their children are the youngest at school entry, a result that is statistically significant at the five percent level. This is a large effect. In context, parents in our sample spend on average 7.5 minutes per day helping their children with school activities. This effect increases to 10 minutes per day when we focus in children 6 to 12 years old, the age window in which parental help in school chores is concentrated (and averages 12.5 minutes per day) and to 15 minutes per day when we exclude summer. Supporting the idea that the differences in parental time investment are related to what happens at school, we do not observe that parents spend more time doing learning activities with their younger children when they are of pre-school age.

Finally, we deepen our analysis by looking at gender differences. Here, we find suggestive evidence of different gender patterns among children from high-SES families. On the one hand, younger boys from high-SES families do not seem to be able to overcome the school entry age disadvantage by the age of 15, and probably because they face a larger disadvantage they receive more parental help with homework and other academic activities, and are more likely to attend schools with better inputs. On the other hand, younger girls from high-SES families do not have different achievement levels at age 15 to their older peers, and probably because they face a smaller disadvantage, they do receive more parental time than older girls from the same SES families, but attend similar schools. We find no such gender specific effect among children from low-SES families.

Our results highlight the importance of considering behavioral responses to policy for the impact evaluation literature based on reduced-form estimates. The reduced-form effects of a policy include both a direct (policy) effect and an indirect effect consisting of endogenous responses to the policy - in our case, parental responses to the school-entry

---

<sup>9</sup>To interpret differences in parental investment by month of birth and SES as differences in parental responses by SES to school disadvantage requires that the relationship between parental inputs and age (month of birth) only varies by SES because the age at school entry penalty. The main concern here would be that low-SES parents decrease faster their time investment than the high-SES parents as their children grow older—this is less of a concern to study responses related to school choice. We show though, in Section 4.4, supporting evidence for this identification assumption.

age (Todd and Wolpin, 2003). To disentangle policy effects and production function parameters, we need to understand behavioural responses to policies. Specifically, we contribute to the emerging literature on parental reactions to school policies (see Das et al., 2013; Fredriksson et al., 2016; Pop-Eleches and Urquiola, 2013).<sup>10</sup> We contribute to this literature by highlighting how these reactions might vary according to parental SES and student’s gender, and by providing more detailed evidence on parental responses. In the closest study to ours, Fredriksson et al. (2016) show that larger class sizes in Sweden increase the likelihood that high-income parents help their children with their homework and low-income parents move their children to a different school. Relative to this paper, we make two contributions. First, we use richer measures of parental investment, which allows to quantify the magnitude of changes in parental time investment, to obtain a more comprehensive picture of changes in school inputs, and to analyze how responses in parental time investments evolve over their children’s life cycle. Second, we look at whether parental responses depend on the interaction between parental SES and their children’s gender.<sup>11</sup>

We also contribute to the ample literature on the effects of age at school entry. Here, we provide novel evidence on a plausible mechanism behind the heterogeneous effect of age at school entry according to SES: differences in parental investment in terms of time and school choice. In a contemporaneous work, Dhuey et al. (2017) use data from the state of Florida in the United States to show that high-SES parents are more likely than low-SES parents to postpone the enrollment of their children in school by one year (a possible practice in that context). Their results support our findings: high-SES parents are more likely to help their children when they are among the youngest at school entry.

The rest of the paper is organized as follows. Section 2 elaborates on the relationship between age at school entry and student outcomes, and describes the institutional framework. Section 3 presents the data and Section 4 the identification strategy. Section 5 describes the results for age at school entry, and Section 6 analyses of parental responses and the differences in these responses according to the child’s age and gender. Section 7 concludes.

---

<sup>10</sup>On the theoretical side, Albornoz et al. (2018) develop a model in which parents compensate for lower educational quality, i.e. public and private investments in a child’s human capital are substitutes.

<sup>11</sup>A related literature analyses how parental investment responds to health endowment at birth. Many empirical studies seem to find evidence suggesting that parental investment reinforces initial differences in health endowments, although there are some indications that high-income parents might be more prone to compensating behavior (see the literature review in Almond and Mazumder, 2013).

## 2 Age at School Entry

### 2.1 How Can Age at School Entry Affect Schooling Outcomes?

The specialized literature has devoted much attention to the issue of how age at school entry can affect student (and adult) outcomes (see, for example, [Crawford et al., 2007](#)). These effects are typically categorized as 1) age at starting school, 2) age at testing, 3) relative age and 4) length of schooling.

1. As age is a determinant of maturity, younger children at school entry might be less ready to acquire knowledge and, overall, to deal with the experience of formal schooling ([Dhuey, 2016](#)). Moreover, because of their age, older students are more likely to have accumulated a higher stock of skills at school entry than their younger classmates, which could also help them to learn more in school.
2. If all the children in a school cohort are examined on the same day, then students are examined at different ages and some students are always younger than their peers.
3. Younger students might perform worse because they are younger than their peers if, for example, differences in absolute performance due to maturity affect the accumulation of skills like self-confidence.
4. The time students spend in the education system might depend on regulations about the timing when students can enter (leave) formal schooling.

The relevance of these effects in shaping student and adult outcomes might depend on the structure of the education system. For example, the level of maturity at school entry is likely to be more important in countries that teach the same (ambitious) curriculum to all students independently of their achievement levels – as is the case in Spain. The same story goes for contexts where grade retention is commonly used – such as Spain. Younger – and less mature – students might be more likely to repeat a grade, which might be detrimental to them if it is associated with negative stereotypes or a loss of self-esteem. The use of (rigid) tracking based on early achievement levels might set younger students on different educational trajectories – ones with access to fewer school inputs – than their older peers ([Mühlenweg and Puhani, 2010](#)). Similarly, age at testing can affect educational trajectories if grades or other measures used to assess student performance are not adjusted for age. [Grenet \(2011\)](#) gives a more complete discussion of how the structure of education systems can amplify initial differences in performance due to age at school entry.

Summing up, their greater maturity and larger human capital at school entry, i.e. higher *school readiness*, can lead older students to perform better initially. If early learn-

ing is complementary to later learning (*dynamic complementarities*) this initial difference in learning outcomes could place early entrants at a permanent disadvantage.

## 2.2 Institutional Framework

### 2.2.1 Age at School Entry

In Spain, children must begin primary school in the September of the calendar year of their 6th birthday. This is an inflexible rule. The birthday cut-off to enter school is January 1st and children are not allowed to postpone entry to school (IEA, 2011). Although it is not compulsory, almost every child attends kindergarten from the September of the year of their third birthday. To illustrate the inflexibility of the Spanish birthday cutoff, we look at children born up to one year before and after a given school birthday cutoff and see if they attend either kindergarten or primary school. To do so, we rely on data from the 2008 to 2016 waves of the Life Conditions Survey (*LCS*, *Encuesta de Condiciones de Vida* in Spanish). This survey is carried out by the Spanish National Institute of Statistics (INE by its Spanish acronym) to gather data on household characteristics.<sup>12</sup> Figure 1 plots the percentage of children enrolled in kindergarten and primary school by month of birth, stacking the 10 birth cohorts available in our data. As it is evident from the graph, compliance with the birthday cutoff rule is strict. Official enrollment statistics confirm this pattern: only 0.5 percent of children who have reached the statutory age for entry into primary education are enrolled in pre-primary education (Eurydice, 2011).

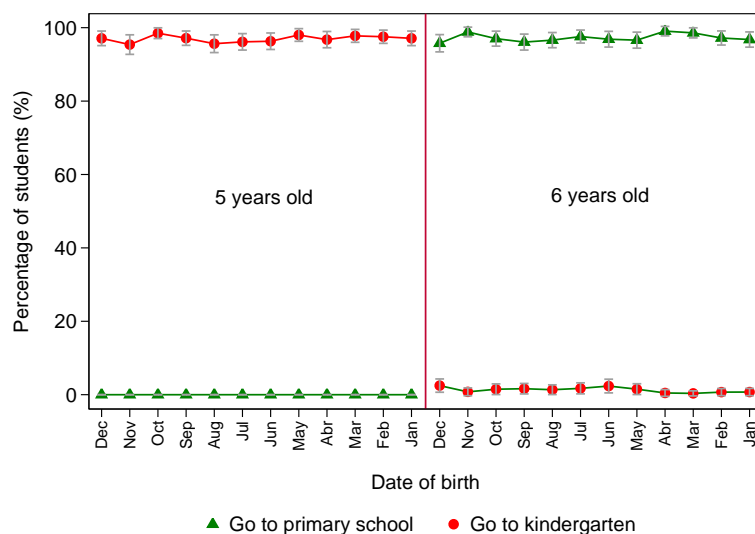

### 2.2.2 Grade Retention

Grade repetition is allowed and common. Students can be obliged to repeat a grade once during primary education (grades 1-6), although some exceptions apply for students with special needs, who can be retained twice. Students can repeat (both) grades 7 and 8; although the total number of repeated years is limited to two in grades 1 to 8. Grade retention is a common practice in both primary and lower secondary school. In fact, Spain is among the three OECD countries with the highest rates of repetition at the primary level (the others are France and Portugal). Similarly, almost a third of students in lower secondary school repeat at least one grade – in contrast to only 0.5% of students in Finland (Eurydice, 2011). Thus, grade retention seems to be commonly used as a remedy for pupils in difficulty in primary and lower secondary education.

---

<sup>12</sup>This is the only publicly available dataset we could find with information on both schooling attendance and month of birth for children aged 5 to 6 years old.

Figure 1: School Enrollment by Schooling Level and Month of Birth: Children 5 and 6 years old

Notes: Data from the 2008 to 2016 waves of the Spanish Life Conditions Survey. The figure plots the percentage of children enrolled in kindergarten and primary school by month of birth. 95% confidence intervals are reported.

### 2.2.3 School Choice

School choice in primary and secondary education is available in Spain since the 1980s. In principle, parents can choose any public or semi-public (*concertada*) school in their municipality of residence for their children to attend. A national law supplemented by province (autonomous-community) regulations dictate the procedures to deal with excess demand for schools. Typically, parents can list a (limited) number of schools in order of preference. Then, central authorities allocate children to schools using an algorithm equivalent to the Boston mechanism, with priorities given on basis of neighborhood of residence, sibling status and socioeconomic characteristics (see details in [Calsamiglia, 2014](#)).

## 3 Data

We analyze data from five different sources. We use micro data from Spanish birth certificates to study birth seasonality. We rely on data from the OECD Programme for International Student Assessment (PISA) and the Spanish population census to analyse the medium- and long-term impacts of the school entry age, respectively. The PISA data also allows us to look at socioeconomic differences in the effect of being younger at school. To analyse the potential mechanisms explaining these socioeconomic differences, we use two different surveys with information about parental investment: the 2009 General Diagnostic Assessment (GDA, *Evaluación General de Diagnóstico* in Spanish) and the

Spanish Time Use Survey (STUS). We use the first of these surveys to study school characteristics and parental help with homework, and the second to study parental time spent on monitoring, teaching and helping children with school-related tasks.

We restrict the analysis of all the datasets to the individuals born in Spain, because seasonality in births (an important element for our identification strategy) can vary across countries.

### 3.1 Spanish Birth Certificates

We use micro data from the universe of Spanish birth certificates from July 2007 to June 2014. The Spanish National Statistical Institute compiles this dataset using the standardized form that families hand in at the time of birth registration. The dataset includes detailed information about the newborn baby (birth weight, method of delivery, gender, an indication of premature birth, among others) and parental demographic characteristics.

We use data starting from 2007 because the information about parental education is only available from that year onwards. We exclude the last semester of 2010 and the first semester of 2011 because [Borra, Gonzalez, and Sevilla \(2015\)](#) show that a temporary policy (a cash transfer) implemented in these years induced changes in birth seasonality. We have 2,462,991 observations in the years included in the analysis and we are left with 2,275,737 (92%) after taking into consideration missing values in the variables of interest. Table A.1 reports summary statistics.

### 3.2 Programme for International Student Assessment

PISA is an international survey run by the OECD that assesses the skills and knowledge of 15-year-old students. We use Spanish data from the 2003, 2006, 2009 and 2012 waves to analyse the relationship between age at school entry and academic performance at age 15, and to study how this relationship varies with family background. In addition to test scores in mathematics and language and data on grade repetition, the survey has information on student socioeconomic characteristics: indices of economic, social and cultural status, parental education, and birthday among others.<sup>13</sup> We obtain a data set with 75,082 observations after pooling the four waves of PISA, from which we keep 74,832 (99.7%) after dropping observations with missing values. Table A.2 shows the summary statistics of the sample analysed.

---

<sup>13</sup>PISA 2006, 2009 and 2012 included an optional questionnaire for parents. However, it was not carried out in Spain.

### 3.3 Spanish Population Census

We use micro data from the 2011 Spanish population census. We download the dataset (10% random sample) from the IPUMS project website, which collects harmonized census data from around the world. We restrict the sample to individuals aged between 30 and 55 at the moment of the census. The database includes information about the individual's education, employment status, marriage status, partner's education (for those married) and month of birth. We obtain a total of 1,437,574 observations and 1,373,194 (95,5%) after leaving out observations with missing values. Unfortunately, the census questionnaire does not include questions about parental background. Table A.3 reports summary statistics.

### 3.4 General Diagnostic Assessment

The Spanish Ministry of Education ran the GDA in 2009 with the purpose of evaluating the general competences of students in grade 4. As part of the assessment, a random sample of grade 4 students took standardized tests in 4 subjects (mathematics, reading, science and civic education), while parents, pupils and school principals answered questionnaires. Our outcomes of interest are mainly those related to parental investment in their children's education. We use information from the surveys of students and parents on whether parents help their children with doing homework, check students' homework and attend school meetings. To analyse parental investment through school choice, we use information on school characteristics (public or private school, class size, teacher profile, etc.) from the survey of school principals (who assess how motivated students and parents in the school are).

The dataset includes information on students' birthdays and we use maternal education (an indicator of whether the mother has a college degree) as a proxy for household socioeconomic status. 887 schools were selected to participate in the study, which covered all fourth-grade students in these schools. The GDA dataset contains 21,738 student observations and 18,583 (85.5%) after taking into account missing responses. Table A.4 shows summary statistics.

### 3.5 Spanish Time Use Survey

We use data from the two waves of the Spanish time use survey (2003 and 2009). Each survey includes a representative sample of the Spanish population. We use information from the diaries of activities reported by all household members older than 10. Each household member older than 10 fills out a diary in which she reports her activities across the previous 24 hours, at 10 minute intervals. They also report whether a child aged 0–9 or another member of the household was present during the activity.

Our outcomes of interest are the time parents spent with their children on the following activities: teaching, reading and playing, and other childcare activities. We construct these variables by adding up the total time that parents report spending on these categories according to their child's age (0 to 9, and 10 to 17 years old). We also have information on individuals' months of birth and their mothers' education (an indicator of whether the mother has a college education). The sample analysed includes households with children (individuals younger than 18). This amounts to 6,286 households in 2003 and 2,356 in 2009. We are left with a total sample of 13,045 children (96.8%) after taking into account missing responses in the variables of interest. Table A.5 shows summary statistics.

## 4 Empirical Strategy

This section presents our empirical approach to analyze how the age at which children begin school affects their performance (at school and also in long-term outcomes), and, more importantly, to study how parents react to this age gap.

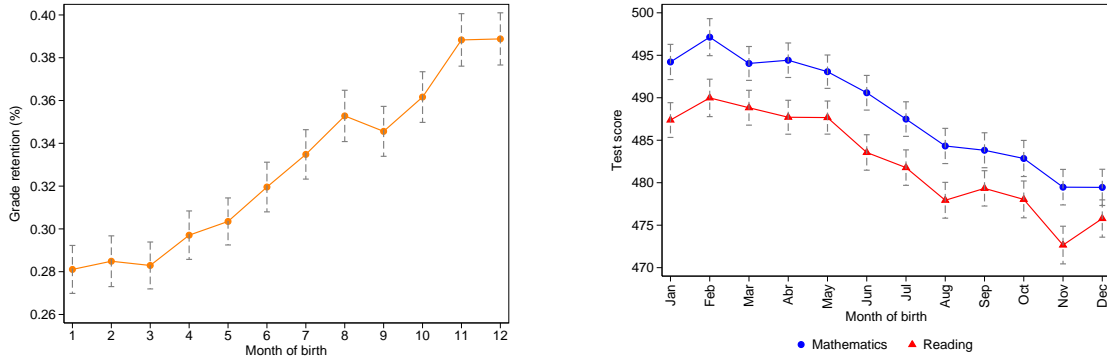

### 4.1 Month of birth and medium- and long-term outcomes

We start by providing evidence on the relationship between the month of birth and student outcomes. Using data from PISA, Figure 2 shows local means of grade repetition and test scores at age 15 by month of birth. There is a clear monotonic relationship between these variables. People born later in the year – and hence who are younger at school entry – tend to perform worse at school, both in terms of grade repetition and test scores. The size of the differences in academic performance between the youngest and the oldest children is large. For example, students born in December (the youngest) are around 10 percentage points more likely to have repeated a grade at age 15 than those born in January (the oldest); and to have test scores around 0.1 standard deviations (SD) lower in both mathematics and reading. These differences are similar to the gender gap observed in this dataset.

We then use the population census to look at the relationship between the month of birth and long-term outcomes. Figure 3 shows local means of the probability of having a college degree by month of birth. In contrast to the PISA data, the relationship between the month of birth and schooling is not monotonic. People born around the middle of the year are more likely to have a college education than others, although the magnitude of the differences between months is small (up to one percentage point). This pattern is difficult to reconcile with a pure age effect – people born in May are younger than people born in January – and suggests the potential existence of seasonality in births. Before turning to explore such a pattern, we describe our econometric specification to clarify our discussion about the identification of the causal effect of age at school entry.

Figure 2: School Performance in Spain and Month of Birth

A. Students who have repeated at least a grade by age 15 (%)      B. Test Scores in mathematics and reading (SD=100)

Notes: Data on Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. The figures plot the share of students who have repeated at least one grade by age 15 and the means of test scores in maths and reading in PISA by month of birth. 95% confidence intervals are reported.

Figure 3: Long-term Outcomes: Month of Birth and College Education

Notes: Data from the 2011 Spanish population census (IPUMS). The sample includes Spanish individuals aged 30 to 55. The figure plots the share of individuals with a college degree. 95% confidence intervals are reported.

## 4.2 Econometric specification

Our identification strategy exploits the variation in age at school entry generated by the combination of using a single birthday cut-off (1st of January) to regulate school entry and the fact that children are born throughout the calendar year. This means that children born after the birthday cut-off (e.g. in January) are older at the moment they start school than children born before the cut-off (e.g. in December). With this relationship in mind, we write the following econometric model:

$$T_i = \alpha_0 + \beta_1 Young_i + \beta_2 High\ SES_i + \beta_3 Young_i * High\ SES + \beta_k X_i' + c_i + \epsilon_i \quad (1)$$

where  $T_i$  is a measure of student/adult outcomes or effort/time investment made by parents of child  $i$ ,  $Young_i$  is a normalized scalar that indicates individual  $i$ 's month of birth,  $High\ SES_i$  indicates whether individual  $i$ 's comes from a family with high socioeconomic status. In most regressions, we proxy this by an indicator that denotes if  $i$ 's mother has a university degree.  $c$  is a vector of birth cohort dummies included when more than one birth cohort is available in the data. The vector  $X'$  includes an indicator for whether  $i$  is a female. The coefficients  $\beta_1$  and  $\beta_3$  are the parameters of interest and indicate the effect of school entry age on the outcomes analyzed for individuals with parents from low ( $\beta_1$ ) and high-SES families ( $\beta_1+\beta_3$ ), proxied by the mother's education.<sup>14</sup>

Interpretation of (differences in) the month of birth as (differences in) the age at school entry depends on parents not manipulating the effective age at which their children start school. In principle, some parents could do this if they are sufficiently concerned about the negative effects associated with the age at school entry. However, as discussed in Subsection 2.2, this strategy is not feasible in the Spanish context. The school system enforces a strict birthday cut-off for school entry so even if they wish to, parents cannot choose this option. In other words, children's predicted school entry age according to their birthday equals their actual age at school entry in Spain.

Causal interpretation of the coefficients  $\beta_1$  and  $\beta_3$  depends on independence between the age at school entry conditional on maternal education and the error term. Broadly, the main threat to identification is that within socioeconomic status (SES) there might be a connection between the month of birth and parental characteristics. This could happen either because some (concerned) parents may plan or postpone births after the birthday cut-off, or, more likely, if mothers with certain characteristics are more likely to give birth in specific months of the year. In this case, the estimated effects of age at school entry would be confounded by birth seasonality. For instance, [Buckles and Hungerman \(2013\)](#) show that in the United States there is such a pattern, as winter births are disproportionally common among teenagers and the unmarried.

To interpret differences in parental investment by month of birth and SES as differences in parental responses by SES to school disadvantage requires that the relationship between parental inputs and age (month of birth) only varies by SES because the age at school entry penalty. The main concern here would be that low-SES parents decrease

---

<sup>14</sup>One alternative strategy is to implement a regression discontinuity design. This option would ideally require to have the exact day of birth, which we do not have in our main dataset. We could still use the month of birth as a discrete running variable and include in the sample individuals born in other months than December and January. Such a choice would have the advantage of increasing sample size and potentially the precision of our estimates. However, misspecification in the control function could lead to bias in the estimated effect. This is an important concern in our case because the documented seasonality suggests that the relationship between cofounders and month of birth is not monotonic. Also, we cannot implement this design in datasets which record mainly students in the same grade, such as PISA and the GDA. Hence, we opt for the more conservative design. Nonetheless, using the STUS data, we also compare individuals born in adjacent January and December months and find similar results, available in Online Appendix, Table B.3.

faster their time investment than the high-SES parents as their children grow older—this is less of a concern to study responses related to school choice. We show though, in Section 4.4, supporting evidence for this identification assumption.

Finally, it is worth noticing that we do not include school fixed effects in our specification, unlike other studies on the effects of school entry age on school performance. As we show in Subsection 6.2, school choice is one possible channel through which parents can respond if their children are among the youngest. Therefore, we do not control for school characteristics.

### 4.3 Birth seasonality: Maternal and Birth Characteristics

Ideally, we would like to study birth seasonality using census-based data from the same birth cohorts for which we observe outcomes. Unfortunately, the available birth certificate data is too recent for such an analysis and, using birth certificate data, we must limit ourselves to studying the cohorts born from the year 2007 onwards. As outlined in the previous subsection, we are primarily concerned about potential seasonality in births according to socioeconomic status SES. Therefore, we look first at the relationship between the month of birth and SES (proxied by maternal education).

Figure 4: Share of Newborns with College-Educated Mothers by Month of Birth

Notes: Data come from Spanish birth certificates. The sample includes the universe of babies born from July 2007 to June 2010 and from July 2011 to June 2014. Local means are represented by dots and 95% confidence intervals are in gray.

Figure 4 plots the local means of maternal education (defined as having a college degree) for children born in each month of the year. We centre the graph around the school entry cut-off (January 1st). As we expected from Figure 3, we find suggestive evidence of birth seasonality by socioeconomic status. Children born from April to June tend to have better educated mothers, while those born in August and September tend to have less educated mothers. However, children born in January and December, close to the birthday cut-off for school entry, have on average mothers with similar levels of education (the 95%-percent confidence intervals of these months overlap). Furthermore, the regression estimate of the difference in average maternal education between the children born in December and January is close to zero (0.002) and is not statistically significant at conventional levels (the standard error is 0.002).

Even if there is no observable connection between maternal SES and the month of birth close to the birthday cut-off for school entry, it is possible that there is a relationship between newborn characteristics and the month of birth within SES if parental characteristics or environmental (institutional) conditions vary by month. To study this possibility, Figure 5 displays the means of several birth characteristics (low weight, premature birth and delivery by c-section) of children born in each month from mothers with (Panel A) and without (Panel B) a college degree. In line with Figures 3 and 4, being born around the middle of the year is associated with more positive outcomes. However, the birth characteristics of children born around the birthday cut-off for school entry seem to be similar both for children from college and non-college-educated mothers.<sup>15</sup> Therefore, from now on we focus our analysis on children born in December and January.<sup>16</sup>

The analysis of birth certificates show that individuals born in December and January are observationally identical in terms of maternal education and several birth characteristics. However, as said before, these individuals were born: 1) in adjacent months, while in our preferred specification we mainly compare individuals born in the same calendar year and 2) in different years than those in our main analysis (the former are younger than the later). Hence, we both: 1) repeat the analysis presented in Section 4.3, but comparing individuals born in the same calendar year; and 2) compare the maternal education and SES of individuals born in December and January in the datasets used in our main analysis.<sup>17</sup> Importantly, the PISA and EGD datasets record mainly (exclusively in the first case) information on people born in the same calendar year. As this amounts to compare people born almost one year apart it is important for us to investigate that they are indeed similar.

---

<sup>15</sup>We confirm this pattern with Table B.2 in the online Appendix, which shows the differences in monthly means by SES of birth characteristics of children born in December and January.

<sup>16</sup>We also look at the density of newborns by month of birth using the same birth certificates data. We do not find any bunching in the number of births by maternal education when we compare those born in December vs January. See Figure B.3 in the online Appendix.

<sup>17</sup>with the exception of the Population Census for which we do not have information on parental characteristics.

Results are reassuring in both exercises. We do not find statistically significant differences between individuals born in January and December in the same calendar year in the STUS, EGD and PISA datasets (which are those used for both our main analysis, in the first two cases, and motivation, in the last case). In the birth certificate data, we find a very small difference, below one percentage point, in maternal education between those born in January and December in the same calendar year, and no differences in new-born characteristics within SES. Details are available in Online Appendix, Table B.1.

Figure 5: New-born Characteristics and Month of Birth

### A. Children of non-college-educated mothers

### B. Children of college educated mothers

*Notes:* Data from Spanish birth certificates. The sample includes the universe of Spanish babies born from non-college educated mothers (first three figures) or from college educated mothers (last three figures) in the period from July 2007 to June 2010 and from July 2011 to June 2014. The figures plot, by month of birth, the percentage of newborns with a low birth weight, the percentage of babies born by cesarean, and the percentage of premature babies. The means are represented by dots and 95% confidence intervals are in gray.

## 4.4 Parental time investment by SES and Age

As said before, our identification strategy would be compromised if the secular rate of change in parental investment by month of birth (age) or grade is different by SES. To be more precise, note that, a larger increase in time investment from high-SES parents in reaction to the age at school entry penalty is observationally equivalent to a secular

pattern in which parents decrease their time investment as their children grow older and such decrease is steeper among low-SES families. Hence, we investigate potential differences in parental investment profiles by age and SES, using data from the Spanish Time Use Survey (STUS).

Figure B.4 in the online Appendix shows the average time (in minutes per day) that parents spend helping their children with academic activities by children's age and SES. As it is possible to observe, high-SES parents spend on average more time teaching their school-age children no matter their child's age. However, and this is the most important feature for us, the evolution of parental time investment by age is similar for parents from high- and low-SES: in both cases it tends to increase during the first years of primary school, reach a peak around age 9 and then go down. This piece of evidence supports our identification assumption that differences in parental investment by SES and month of birth in individuals from a same birth cohort are not explained for differences by SES in parental investments along the life-cycle.

## 5 The Effect of Being the Youngest

In this section, we present the reduced-form effects of age at school entry on student and adult outcomes. Our main specification only includes individuals born in January or December to avoid problems related to birth seasonality in children and maternal characteristics. First, we examine the average effects on medium- and long-term outcomes, using data from PISA and Spanish population census, respectively. Then, in Subsection 5.2, we analyze whether these effects vary by socioeconomic status.

### 5.1 Poor Little Children: Short and Long-Term Effects of Being the Youngest

Columns 1-3 in Table 1 present the results of regressing several measures of school performance (grade retention, maths and reading test scores) on an indicator of whether the student was born in December or in January, an indicator for being a female and an indicator for coming from a family with a high socioeconomic status (in the top 25% of the distribution of the SES index). All the regressions include vectors of dummies for the year of birth and the PISA survey year. Remember that the oldest children in a class are born in January ( $Young = 0$ ) and the youngest children are born in December ( $Young = 1$ ).

Along the same line as the visual evidence, younger students do worse in school than their older peers. The youngest children in their cohort are 10 percentage points more likely to have repeated a grade at age 15 than the oldest children (Column 1). This gap is similar to the gender gap in grade retention (see row 2, also in Column 1), and around 2/5 of the estimated gap for socioeconomic status (see row 3). In the same fashion, there

is a clear age gap in student achievement as measured by standardized test scores. On average, the youngest students have lower test scores in mathematics (-0.14 SD) and in reading (-0.11 SD). All the results discussed are statistically significant at the one percent level.

Table 1: **Medium- and long-term outcomes**

	Medium-term outcomes			Long-term outcomes		
	Grade retention (1)	Maths score (2)	Reading score (3)	College graduate (4)	Employed (5)	Partner has college degree (6)
Young	0.105*** (0.014)	-13.861*** (2.476)	-11.164*** (2.370)	-0.00599*** (0.00198)	0.00152 (0.00247)	-0.00729*** (0.00216)
Female	-0.086*** (0.014)	-11.568*** (2.464)	34.421*** (2.496)	0.0281*** (0.00195)	-0.125*** (0.00243)	-0.00791*** (0.00211)
Top 25% SES	-0.259*** (0.015)	59.506*** (2.797)	53.436*** (2.763)			
Mean	0.28	499.25	491.24	0.143	0.680	0.119
Observations	12,311	12,311	12,311	226,454	226,454	162,920

*Notes:* The data analysed in columns 1 to 3 come from Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. In these first three columns the outcome variables are indicators of school performance. Grade retention (Column 1) indicates whether the student repeated a grade at least once, and maths and reading scores (columns 2 and 3) represent the student’s performance in the PISA tests. The data analysed in columns 4 to 6 come from the 2011 Spanish population census. In Column 4, the outcome variable is an indicator of whether the individual is a college graduate, in Column 5 it is an indicator of whether s/he is employed, and in Column 6 an indicator of whether her/his spouse is a college graduate. The sample includes Spanish individuals born in December and January. “Young” is an indicator variable that equals one if the student was born in December and equals zero if s/he was born in January. The regressions presented in columns 1 to 3 include survey year dummies and those presented in columns 4 to 6 include cohort dummies, where the cohorts are defined as being born from July to June of the following year. Robust standard errors are in parentheses (clustered at school level in the case of columns 1 to 3). \* p<0.10, \*\* p<0.05, \*\*\* p<0.01.

Columns 4-6, also in Table 1, present the results for the long-term effects of being an early entrant to school using data from the Spanish population census. The sample analysed includes individuals born in December and January. We do not include information on parental SES because we do not observe this information in the census data. All the regressions include birth cohort dummies. Note that the birth cohorts here are defined to compare individuals born in adjacent months (we cannot do this for the PISA data because we would compare students in different grades). We find that people born in January (the oldest at school entry) are more likely to have a college degree (by 0.6 percentage points) and to have a more educated partner (one with a college degree, by 0.7 percentage points) than people born in December (the youngest at school entry). Both

results are statistically significant at the 1 one percent level. We do not find statistically significant differences in the probability of being employed. Summing up, Table 1 documents that – in line with the international literature - people who are younger at school entry tend to have worse student outcomes, which seems to translate into the long term. We now move on to analyse differences by parental SES.

## 5.2 Socioeconomic Status and the Disadvantages of Being Younger: Poor (Poor) Little Children

Table 2 shows the results of regressing measures of student performance on an indicator of whether the student was born in December or January, an indicator for being a female, an indicator for coming from a family in the top 25% of the distribution of the SES index, and an interaction term between these two indicators (*Young \* top 25%*).

We find clear differences in the effect of age at school entry by socioeconomic background. Being young is significantly worse for the poor. Young students from a low socioeconomic background are 12.7 percentage points more likely to have repeated a grade at age 15 than older students from the same socioeconomic background (see row 1 in Column 1). Importantly, this age effect is significantly smaller for children with a high socioeconomic background, by 8.7 percentage points (see Row 4). A qualitatively similar argument can be made about achievement at age 15, as measured by test scores in maths and reading. Young students from a low socioeconomic background have -0.16 SD (-0.14 SD) lower maths (reading) test scores than their older counterparts (see Row 1, Columns 2-3), while this age effect is significantly smaller for privileged children: 0.1 SD in both subjects. These results are statistically significant at the one percent level. Still, young children from high socio-economic status are more likely to have repeated a grade (by 4 percentage points) and have lower math test scores (by 0.06 SD) at age 15 than older students from the same socioeconomic background (see Row 6-7, Columns 1-2), though they have statistically similar reading test scores (Row 7, Column 3). Overall, we find similar results when using the Index of SES as a continuous variable. See Figure B.1 in the online Appendix.

Therefore, families with a high socioeconomic status seem to buffer the negative effect of being relatively young on their children’s outcomes, while those with a lower socioeconomic background do not. In Section 6 we discuss two potential mechanisms behind this result and analyse data on parental involvement in their children’s education to study whether parents respond differently to age at school entry depending on their SES.

Table 2: School performance, entry age and socioeconomic status

	Grade retention (1)	Maths score (2)	Reading score (3)
Young	0.127*** (0.018)	-16.439*** (2.983)	-13.754*** (2.842)
Female	-0.086*** (0.014)	-11.553*** (2.460)	34.435*** (2.493)
Top 25% SES	-0.215*** (0.019)	54.408*** (3.789)	48.317*** (3.778)
Young * top 25% SES	-0.087*** (0.028)	10.153*** (5.378)	10.195*** (5.187)
Mean	0.28	499.25	491.24
$\beta_1 + \beta_3$	0.04	-6.29	-3.56
p-value: $\beta_1 + \beta_3 = 0$	0.014	0.028	0.21
Observations	12,311	12,311	12,311

*Notes:* Data from Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. The outcome variables are indicators of school performance. Grade retention (Column 1) indicates whether the student repeated a grade at least once, and maths and reading scores (columns 2 and 3) represent the student’s performance in the PISA tests. “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if s/he was born in January. Young \* top 25 SES ( $\beta_3$ ) is an indicator of the interaction between the variable “Young” and an indicator for coming from a family in the top 25% of the distribution of the SES index. All regressions include year dummies as controls. Standard errors clustered at the school level are in parentheses. \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

## 6 Parental Responses

Two channels could explain why entry age effects are greater among children from low-SES families. First, high-SES children might actually be ready to start school irrespective of their age. Note that high-SES children are likely to be more ready to start school than low-SES children, because of the well-established correlation between family SES and pre-school investment. This explanation implies that what puts young children at a learning disadvantage is being below a minimum level of achievement (maturity) on the first day of school and that growing up in a more nurturing environment makes it more likely that even the youngest children are above this minimum level.

Second, high-SES parents might increase their investment when their children are among the youngest at school entry to compensate for their learning disadvantage. Parents with higher SES are likely to be more prepared in terms of financial resources, human capital and information to invest in their children in reaction to a negative shock. A dominance of channel one implies that among high-SES families one should not observe differences in parental investment according to the child’s age at school entry. A domi-

nance of channel two implies the opposite. In this section, we analyze data on parental involvement in their children’s education to study whether parents respond differently to age at school entry depending on their SES.

We begin the study of parental time investment by using data from the Spanish Time Use Survey (STUS) and the General Diagnostic Assessment survey (GDA). Then, using the second of these surveys, we analyze whether parents choose schools with different inputs when their children are younger at school entry. Finally, we investigate whether parental responses vary according to the age and the gender of children.

## 6.1 Parental Time Investment

Our main estimates on parental time investment come from data from the two waves of the Spanish time use surveys. The STUS reports detailed use of the time that parents spend participating in activities directly related to their children’s human capital development.

Table 3 reports the estimated coefficients from Equation 1 using as outcomes measures of the time (in minutes) that parents spend teaching their children, reading and playing with them, and on other childcare activities. These coefficients represent the effects of age at school entrance on parental time investments and how such effects interact with family socioeconomic status (i.e. whether the mother has a college education or not).

Table 3: Parental Time investment

	(1)	(2)	(3)
	Teaching	Read and Play	Other childcare
Youngest	-0.228 (1.156)	0.644 (2.349)	-4.367 (4.967)
College mother	0.531 (1.481)	6.402* (3.394)	13.17* (7.222)
Youngest X College mother	5.233** (2.553)	-1.686 (4.415)	-5.322 (9.659)
Girl	0.476 (1.035)	-1.345 (1.995)	-5.739 (4.104)
Mean	7.55	22.64	85.74
$\beta_1 + \beta_3$	5.01	-1.04	-9.69
p-value: $\beta_1 + \beta_3 = 0$	0.03	0.78	0.24
Observations	2,196	2,196	2,196

*Notes:* Data from the Spanish Time Use Survey 2003 and 2009. The sample consists of children aged 0 to 17 born in December or January in Spain. The outcome variables indicate the minutes parents spent daily with their children doing different activities: ones related to teaching (Column 1), reading and playing (Column 2), and other childcare activities (Column 3). “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has more than secondary education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. All the reported models include a vector of dummies for year of birth, and day of week and quarter of interview. Standard errors are clustered at the household level. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

In households with non-college-educated mothers, the school entry age does not seem to affect parental time investment in activities related to children’s human capital development. The coefficient for being the youngest in the three regressions presented has a small magnitude and is not statistically significant at conventional levels. In contrast, households with university-educated mothers do spend significantly more time with their children on activities related to teaching (+ 5 minutes per day, significant at the five percent level) than their older peers from similar types of families. This is a large effect. In context, parents in our sample spend on average 7.5 minutes per day helping their children with school activities. There are not statistically significant differences according to children’s month of birth in the time that highly educated parents spend on the other childcare activities. Thus, more educated parents compensate by investing more time in teaching activities when their children are among the youngest in their school cohort. Interestingly, this effect seems to be larger during the school months (estimate is 7 minutes, see Table B.4 in the online Appendix).

We complement these results with data from the General Diagnostic Assessment survey. Here, using self-reported statements, we analyze whether parents respond to school entry age by changing their behaviour regarding helping children with their homework, checking their homework, or by attending school meetings more frequently (as reported by the students). As before, we examine whether the parental responses depend on maternal education.

Table 4: Parental Involvement

	(1) Help with homework	(2) Parents check homework	(3) Parents go to school meetings
Young	0.00447 (0.0154)	0.00354 (0.0190)	-0.0228 (0.0201)
College mother	0.0349* (0.0192)	-0.108*** (0.0271)	-0.0267 (0.0275)
Young X College mother	0.0750*** (0.0247)	0.0724** (0.0364)	0.0425 (0.0377)
Girl	-0.0152 (0.0123)	0.0327** (0.0166)	-0.00897 (0.0169)
Mean	0.85	0.69	0.59
$\beta_1 + \beta_3$	0.079	0.076	0.02
p-value: $\beta_1 + \beta_3 = 0$	0.00	0.02	0.54
Observations	3461	3350	3345

*Notes:* The data comes from the General Diagnostic Assessment survey of 2009. The sample includes Spanish students enrolled in 4th grade who were born in December or in January. The outcome variables are different measures of parental involvement in children’s education: a variable indicating whether parents help their children with the homework (Column 1), an indicator variable of parents checking children’s homework (Column 2), and a variable indicating whether parents frequently go to school meetings (Column 3). “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has a college education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. Standard errors are clustered at the school level. \* p<0.10, \*\* p<0.05, \*\*\* p<0.01

Table 4 presents the estimated coefficients from Equation 1 in which the outcome variables are indicators of different dimensions of parental involvement. As in the time use

data, we do not find that households with non-college educated mothers invest differently if their children enter school at a younger age (first row of Column 1); and, we do find differences in households with college-educated mothers. Children from university-educated mothers are significantly more likely to receive help to do their homework (+ 8 percentage points, significant at the 1 percent level) and to have their parents check their homework (+7.6 percentage points, significant at the five percent level) than their older peers from similar types of family (see Rows 6-7 in Columns 1-2). We do not find more likely though that their parents go to school meetings (Column 3). Summing up, this evidence shows that more educated parents compensate for school disadvantage by putting more effort into helping their children with their with academic tasks.<sup>18</sup>

## 6.2 School Choice

We now analyse whether parents respond to school entry age by sending their children to schools with different levels of inputs, and whether these reactions vary according to the level of maternal education.

Using the General Diagnostic Assessment, we look at differences in several school inputs between the schools that students born in December and January attend. To do this, we rely on the principal and teacher survey questionnaires. Table 5 presents the coefficient estimates from Equation 1. In the first column, the outcome is an indicator variable of whether the student attends a *concertada* school: a privately-managed school, which may offer a more customized education environment than regular schools.<sup>19</sup> We do not find that entry age significantly affects school choice regarding this specific feature, independently of the mother’s education. However, younger children with college-educated mothers are more likely to attend schools with better teachers (+ 0.09 SD in a teacher quality index significant at the one percent level) and with parents more involved in the school (+ 0.088 SD in a parental involvement index, significant at the five percent level) than their older peers from similar types of families (Row 6, Columns 4-5). In contrast, we do not observe significant differences in the characteristics of the schools attended by children from mothers without a college education (see the first row in Columns 1-5). In the online Appendix we provide the disaggregated effects of the variables that constitute the Teacher Quality and the Parental Involvement indexes, plus a School Quality Index, which aggregates the nine variables analysed (which shows results consistent with those presented in Table 5). It is also worth to notice that we find effects in both variables reported by teachers (Parental Involvement Index) and principals (Teacher Quality). The principals assesments refer to overall teacher quality at the school level, not the teacher

---

<sup>18</sup>We also compare individuals born in adjacents January and December months and find similar results, available in Online Appendix, Table B.3.

<sup>19</sup>According to figures from Eurostat for Spain, 68% of primary school students attend public schools, 28% *concertada* schools and 4% fully private schools.

in the specific classroom that the child attends. This is relevant because supports the argument that high-SES parents choose schools with better inputs when their children are the youngest at school entry—in contrast to an alternative explanation in which younger high-SES children are sorted into better classrooms either because in general high-SES children attend more responsive schools or because parents lobby for better classrooms rather than choosing better schools. Therefore, we find evidence that more educated parents are more likely to send their children to schools with better inputs when they enter school at an earlier age.<sup>20</sup>

Table 5: School Quality

	(1)	(2)	(3)	(4)	(5)
	<i>Concertada</i> school	Class size	Peers motivated to learn	Teacher quality index	Parental involvement index
Young	0.00284 (0.0204)	0.214 (0.179)	-0.0256 (0.0214)	-0.00598 (0.0244)	-0.00791 (0.0304)
College mother	0.232*** (0.0299)	1.325*** (0.289)	0.138*** (0.0271)	0.00358 (0.0319)	-0.00558 (0.0417)
Young X College mother	0.0361 (0.0370)	-0.576* (0.338)	0.0669** (0.0332)	0.0984** (0.0431)	0.0960** (0.0485)
Girl	0.0164 (0.0170)	0.136 (0.141)	-0.00876 (0.0161)	0.00822 (0.0203)	0.00959 (0.0221)
Mean	0.40	23.89	0.69	0.01	0.02
$\beta_1 + \beta_3$	0.039	-0.362	0.041	0.092	0.088
p-value: $\beta_1 + \beta_3 = 0$	0.23	0.19	0.13	0.01	0.04
Observations	3171	3171	3171	3171	3171

*Notes:* The data come from the General Diagnostic Assessment survey 2009. The sample includes Spanish students enrolled in grade 4 who were born in December or January. The outcome variables are different school characteristics: a *concertada* school indicator (Column 1), class size (Column 2), an indicator of whether the teacher reports that the students in her class are very motivated (Column 3), a Teacher Quality Index (Column 4) and a Parental Involvement Index (Column 5) “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has a college education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. Standard errors are clustered at the school level. \* p<0.10, \*\* p<0.05, \*\*\* p<0.01

Overall, these results are consistent with the idea that more educated parents compensate when their children start school at an earlier age by spending more time helping their children with school and sending their children to schools with better inputs. Along the same lines, we do not find that less educated parents change their patterns of investment in their children to compensate for or reinforce the effects of entry age. This socioeconomic difference in compensating behaviour helps to explain why the detrimental effect of being young at school entry is greater for low-SES children.

<sup>20</sup>Also in the General Diagnostic Assessment, both parents and students declare (in separate surveys) if the student is enrolled in her current school because she lives in the school’s catchment area. We use this information as an indicator that parents choose (or not) to send their young children to different schools from the default option. We find that children from mothers without a college education seem to go to their neighborhood school regardless of the month when they were born, while young children from college-educated mothers seem to be more likely to attend a different school to the default option than the older children from similarly educated mothers. Table B.6 in the online Appendix reports the results.

## 6.3 Heterogeneity Analysis

### 6.3.1 Parental Time Investment according to Age

Using data from the Time Use survey, Table 6 reports the estimated coefficients from Equation 1 for three age groups: children younger than 6 (who are below school age at the moment of the survey), children aged 6 to 12 (who are of primary school age), and children aged 13 to 17 (who are of secondary school age). Table 3 shows that young children with highly educated mothers spend more time with their parents on activities related to teaching than their older peers. If these results are driven by a mere age effect and not by what is going on in school (i.e. not by a negative early entry age effect), we might expect a similar pattern if we analyse the sample of children who are outside of compulsory school age. However, as shown in Table 6 (row 6 in columns 1–3), the sum of the coefficients for *Young* and the interaction *Young\*College Mother* is not significantly different from zero when estimated using the sample of children aged 0 to 5. This includes both parental time related to teaching and all other childcare. In contrast, the coefficient for this interaction in the teaching time regression is positive and statistically significant when we analyse the sample of children who are above school entry age, i.e. aged 6 to 12 (Column 4) and 13 to 17 (Column 7).

Interestingly, the magnitude of the point estimate in the sample of children aged 6 to 12 seems to be larger than that in the sample of children aged 13 to 17. While in the former sample the youngest children from households with university-educated mothers spend 10 minutes more a day with their parents on activities related to teaching than their older peers, in the latter sample the corresponding figure amounts to only 7 minutes (and it is, marginally, insignificant). This pattern is consistent with the ideas that 1) parents react to their realization that their child has a school disadvantage, and 2) that the returns on investments at earlier ages are larger. This is only suggestive evidence as we do not have enough statistical precision to rule out that both parameters are of the same magnitude. As Table B.5 in the online Appendix shows, the compensating effect becomes larger when we exclude the summer months (point estimate is 15 minutes), which reinforces the idea that parental reactions are driven by what is going on in school. Once more, across the three age groups we observe that in households with more lowly educated mothers entry age does not seem to affect parental time investment in activities related to children's human capital development.

*Notes:* Data from the Spanish Time Use Survey 2003 and 2009. The sample is of children aged 0 to 17 born in December or January in Spain. The first 3 columns include only children younger than 6, columns 4 to 6 include children aged 6 to 12 and the last 3 columns include children aged 13 to 17. The outcome variables indicate the minutes a day parents spent with their children doing different activities: ones related to teaching, to reading and playing, and other childcare activities. “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has more than secondary education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. All the reported models include a vector of dummies for year of birth, and day of week and quarter of interview.. Standard errors are clustered at the household level. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

### 6.3.2 Gender Differences

Finally, we analyse whether the responses from highly- and poorly-educated parents vary according to the student’s gender. We look at gender gaps motivated by the literatures that show that girls mature faster than boys (see a discussion in [Bertrand and Pan, 2013](#)), and that boys struggle more when they face disadvantaged environments (see for example in the literature on family structure: [Figlio et al., 2016](#); [Fan et al., 2015](#)). To do this, we first analyze whether the age effect on student outcomes, as measured by PISA, differs with gender. We find some evidence, which is reported in Table 7, that this is the case. As before, we observe that being among the youngest at school entry has a significant negative effect among children from low-SES families, both for boys and girls (see row 1, columns 1-6). However, the story seems to be different for children from high-SES families. On the one hand, boys from high-SES families do not seem to manage to overcome the age disadvantage (see rows 5 and 6, Columns 1-3). Compared to their older peers, young boys from high-SES are more likely to have repeated a grade (by 7.4 percentage points, with statistical significance at the one percent level) and to have lower test scores in math (by 0.11 SD, with statistical significance at the one percent level) and reading (by 0.08 SD, with statistical significance at the ten percent level) at age 15. In contrast, we do not observe a gap in student outcomes among high-SES girls (Columns 4-6). The magnitude of the coefficients reported in Row 5 is small and none is statistically significant at conventional levels (see Row 6). Therefore, at age 15, there are no differences in academic performance between December- and January-born girls who come from advantaged families.

Table 7: School Performance by Student Gender

Observations	6070	6070	6070	6241	6241	6241

*Notes:* Data from Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. The first 3 columns correspond to the analysis of the sample of boys and the last 3 to the sample of girls. The outcome variables are indicators of school performance. Grade retention (Column 1) indicates whether the student repeated a grade at least once, and maths and reading scores (column 2 and 3) represent the performance of the student in the PISA tests. “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and zero if she was born in January. Young \* top 25 SES ( $\beta_3$ ) is an indicator of the interaction between the variable “Young” and an indicator for coming from a family in the top 25% of the distribution of the SES index. All regressions include year dummies as controls. Standard errors clustered at school level are in parentheses. \* p<0.10, \*\* p<0.05, \*\*\* p<0.01

We use data from the General Diagnostic Assessment to study differences in parental investments by SES and gender because this data has a larger sample size than the

Spanish time use surveys. Table 8 shows that young boys from households with university-educated mothers are more likely to receive help from their parents with homework (by 6 percentage points) and their parents are more likely to check their homework (by 10 percentage points) – see Rows 5 and 6 in Columns 1-2. Both younger girls from low- and high-SES are more likely to receive help with homework from their parents with respect to their older peers (by 4 percentage points, at the ten percent level, in the first case, and by 10 percentage points, at the one percent level, in the second case). Though we do not observe these differences in the probability that parents check their homework and go to school meetings (Columns 5–6).

We obtain results along the same lines using data from the Spanish time use surveys. Although the results are more imprecisely estimated, we observe again that the differential compensating effect on time investment found among high-SES parents is mainly present in male students (see the results in Table B.8 in the online Appendix). We also look at gender differences in school choice.(see Table 9 ). Again, it stands out that younger boys from high-SES are more likely to be enrolled in schools with better inputs with respect to older boys from families of similar background (Panel A, Rows 5-6). There are no observed differences between the schools attended by young vs old boys from low-SES (Panel A, Row 1), nor girls from both high- and low-SES (Panel B)

To summarise, we do not find that the student outcomes or the parental responses for boys and girls from low-SES families differ according to the age at school entry. In contrast, we observe different gender patterns among children from high-SES families. On the one hand, younger boys from high-SES families do not seem to be able to overcome the age at school entry disadvantage by age 15, and probably because they face a larger disadvantage they receive more parental help with homework and other academic activities. On the other hand, younger girls do not have different achievement levels at age 15 to their older peers, and probably because they face a smaller disadvantage, we only observe that they receive more parental time than older girls from the same SES families, but they attend similar schools. Maybe girls mature faster than boys, or receive more investment than boys, and do not face a learning disadvantage at school entry, or they are able to overcome this disadvantage faster. We cannot say which of these explanations is true, but these results indicate, like those presented before, that high-SES parents invest more in their children when they are at a disadvantage at school.

Table 8: Parental Involvement by Student Gender

*Notes:* The data comes from the General Diagnostic Assessment survey 2009. The sample includes Spanish students enrolled in 4th grade who were born in December or in January. Columns 1 to 3 analyse the sample of boys and columns 4 to 6 the sample of girls. The outcome variables are different measures of parental involvement in children's education: a variable indicating whether parents help their children with their homework (Column 1), an indicator variable of parents checking children's homework (Column 2), and a variable indicating whether parents frequently go to school meetings (Column 3). "Young" ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and zero if she was born in January. The variable "College mother" takes value 1 if the mother of the student has a college education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between "Young" and "College mother". Standard errors are clustered at the school level. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

*Notes:* The data come from the General Diagnostic Assessment survey 2009. The sample includes Spanish students enrolled in 4th grade who were born in December or January. Panel A analyses the sample of boys and Panel B the sample of girls. The outcome variables are different school characteristics: a *concertada* school indicator (Column 1), class size (Column 2), an indicator of whether the teacher reports that the students in her class are very motivated (Column 3), a Teacher Quality Index (Column 4) and a Parental Involvement Index (Column 5). “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has a college education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. All reported models include a vector of dummies for birth cohort. Standard errors are clustered at the school level. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

## 7 Conclusions

To understand inequality in human capital it is necessary to understand how parental investment varies according to socioeconomic status. Our results contribute to this goal by providing evidence on how parents can react to a widely-used school policy that puts younger children at a learning disadvantage. They are consistent with the idea that parental responses vary with socioeconomic status.

Highly-educated parents compensate when their children enter school at an earlier age by spending more time helping their children with learning activities and choosing schools with better inputs for them, when their children enter school at an earlier age. We do not find a similar pattern among less educated parents. This socioeconomic difference in behavior can potentially explain why the disadvantage of being young at school entry is greater for children from disadvantaged backgrounds. Interestingly, the response of highly educated parents is particularly present in the case of boys.

There is a well-established empirical relationship between parental socioeconomic status and student (and longer-term) outcomes. Differences in planned investment paths are likely to play a key role in this. Our results highlight an additional channel: differences in investment due to different responses according to parental background to policies (or potentially life shocks) that put children at a learning disadvantage. In other words, we find evidence that more educated parents are more prepared to handle disadvantage and can then protect their children from it by increasing the resources they allocate to them.

Our findings call for the design of public policies targeting those who need support the most: young children from low-SES families, presumably with a focus not only on the children, but also on parents and schools.

The results presented in this paper are also informative about the effects of teaching the same curriculum to children with different achievement levels, which is a common practice across countries. Our findings suggest that the task of dealing with a unique curriculum from the position of a learning disadvantage can be particularly daunting for children from low-SES families. Policies aiming to allow schools to teach at the right level (using some degree of tracking or supplementary activities according to achievement level) are worth exploring.

Reading	492.3 (83.64)	491.2 (84.72)
Observations	74,832	12,311

*Notes:* Data on Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. Repeater is an indicator of whether the student repeated a grade at least once, and maths and reading scores represent the performance of the student in the PISA tests. Column 1 reports means and the standard errors, in parentheses, for the full sample and Column 2 for those born in December and January.

Table A.3: Spanish Population Census: Summary Statistics

	(1)	(2)
	All	Dec and Jan
Age	42.82 (7.312)	42.60 (7.346)
Female	0.501 (0.500)	0.501 (0.500)
College graduate	0.145 (0.352)	0.143 (0.350)
Employed	0.684 (0.465)	0.680 (0.466)
Married	0.637 (0.481)	0.637 (0.481)
Partner is college graduate	0.121 (0.326)	0.119 (0.324)
Observations	1,373,194	226,454

*Notes:* Data from the 2011 Spanish Census (IPUMS). The sample includes Spanish individuals born in December and January aged 30 to 55 at the moment of the census. The variables are indicator dummies of whether the individual is a college graduate, whether s/he is married, and whether s/he was employed at the moment of the census. Column 1 reports means and the standard errors in parentheses for the full sample and Column 2 for those born in December and January.

Table A.4: General Diagnostic Assessment: Summary Statistics

	(1)	(2)
	All	Dec and Jan
Girl	0.499 (0.500)	0.495 (0.500)
College mother	0.298 (0.457)	0.304 (0.460)
Help with homework	0.861 (0.346)	0.856 (0.351)
Parents check homework	0.693 (0.461)	0.687 (0.464)
Parents go to school meetings	0.579 (0.494)	0.586 (0.493)
Concertada school	0.396 (0.489)	0.401 (0.490)
Class size	23.90 (3.901)	23.87 (4.067)
Peers motivated to learn	0.704 (0.456)	0.691 (0.462)
Parental interest in learning problems	0.284 (0.451)	0.289 (0.453)
Parental interest in grades	0.385 (0.487)	0.384 (0.487)
Parents attend meetings	0.481 (0.500)	0.481 (0.500)
Teachers continual training	0.791 (0.406)	0.789 (0.408)
Teachers target students with learning disadvantages	0.604 (0.489)	0.616 (0.486)
Teachers follow students' progress daily	0.704 (0.456)	0.706 (0.456)
Observations	18,583	3,085

*Notes:* The data comes from the General Diagnostic Assessment survey 2009. The sample includes Spanish students enrolled in 4th grade. The variable “college mother” takes value 1 if the mother of the student has a college degree and zero otherwise. “Concertada school” takes value 1 if the school is privately managed and is zero otherwise. Class size indicates the number of students in the class. The rest of the variables are indicators about parental involvement in their children education (measured in a student survey) and school inputs (measured in surveys to parents and school principals). Column 1 reports means and standard deviations in parentheses for the full sample and Column 2 for those born in December and January.

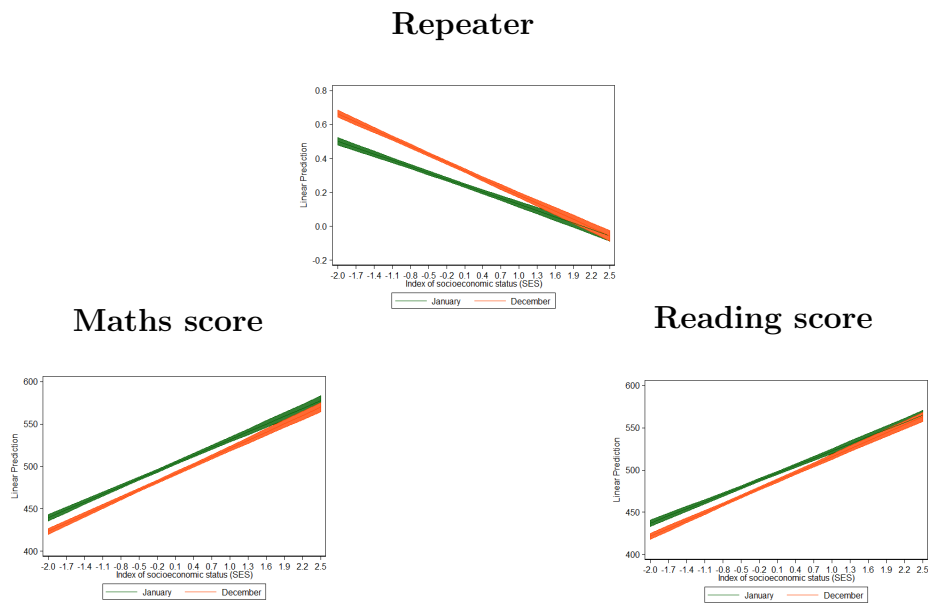

Table A.5: Spanish Time Use Surveys 2003 and 2009: Summary Statistics

	(1)	(2)
	All	Dec and Jan
Girl	0.484 (0.500)	0.500 (0.500)
College mother	0.364 (0.481)	0.364 (0.481)
Time spent teaching	7.690 (25.51)	7.546 (24.88)
Time spent reading and playing	22.71 (53.28)	22.64 (51.98)
Childcare time	86.21 (118.9)	85.74 (118.6)
Observations	13,045	2,196

*Notes:* Data from the Spanish Time Use Survey 2003 and 2009. The sample is of children aged 0 to 17 born in Spain. The variable “college mother” takes value 1 if the mother of the student has a college degree and zero otherwise. The other variables indicate the minutes a day parents spent with their children doing different activities: ones related to teaching, reading and playing, and other childcare activities. Column 1 reports means and standard deviations, in parentheses for the full sample and Column 2 for those born in December and January.

# Online Appendix

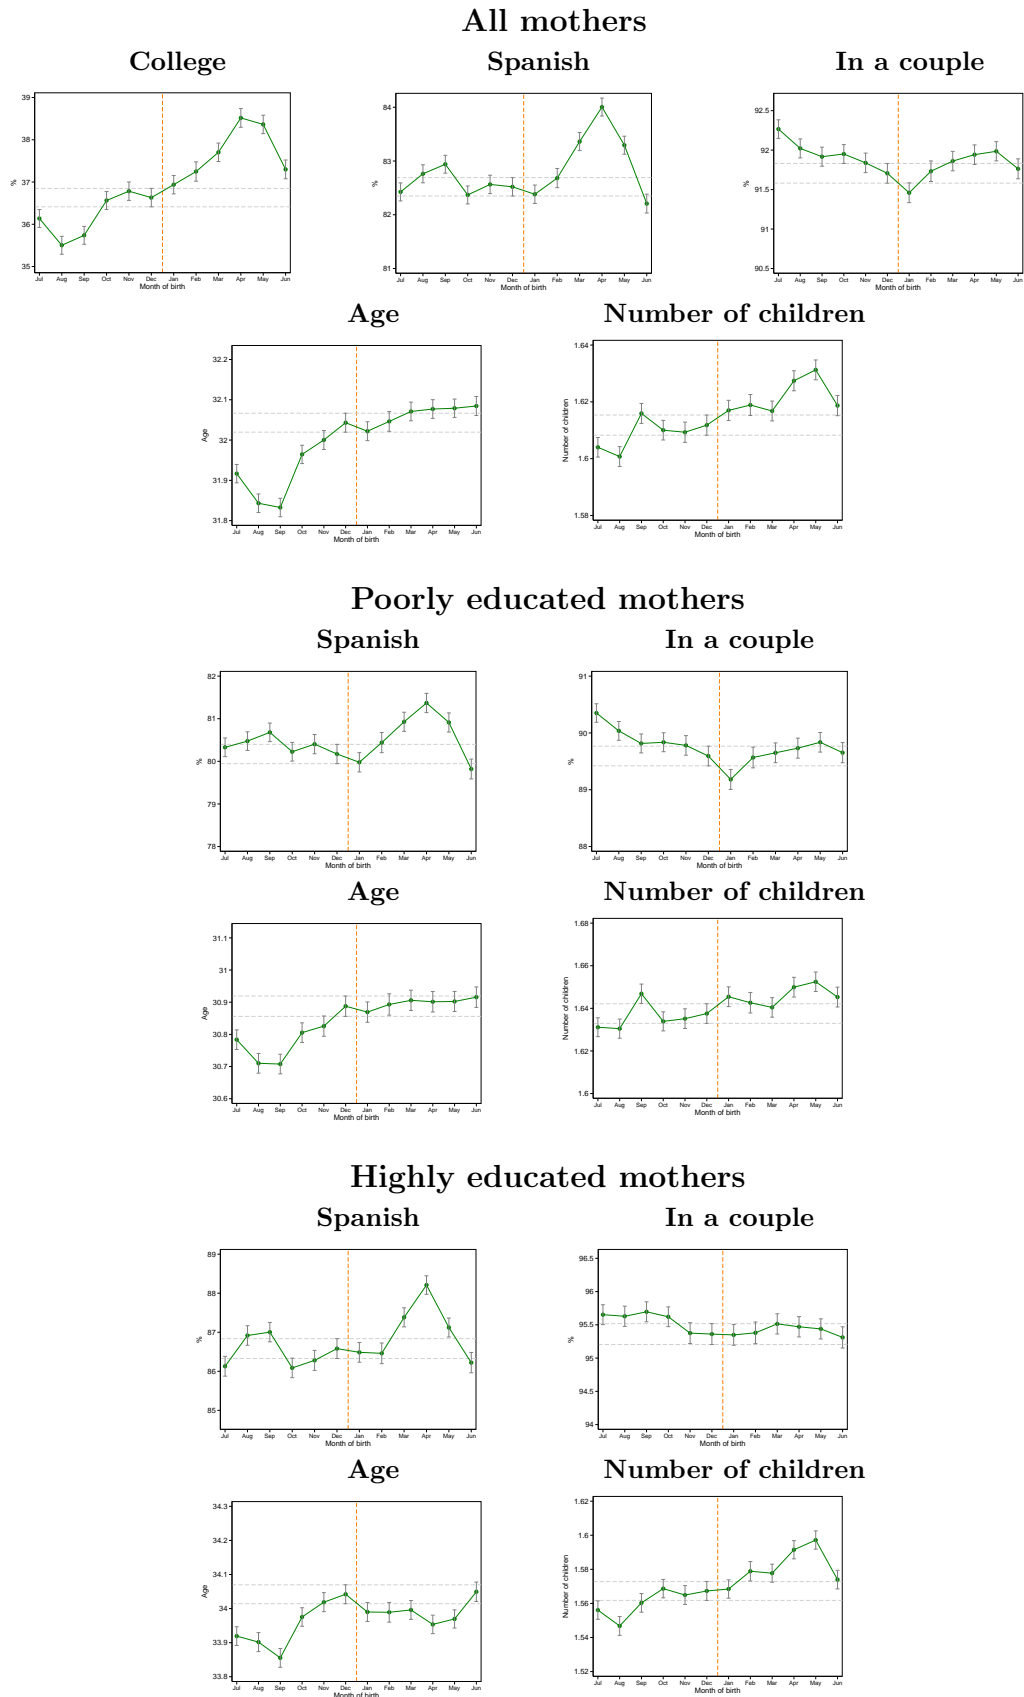

Figure B.1: School Performance at age 15: Young vs. Old According to SES

Notes: Data on Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. For young (born in December) and old (born in January) students the figures plot the predicted marginal effect of socio-economic status on: the probability of having repeated at least one grade (top), and the mean test score in maths and reading at PISA (bottom). Point estimates and 95% confidence intervals.

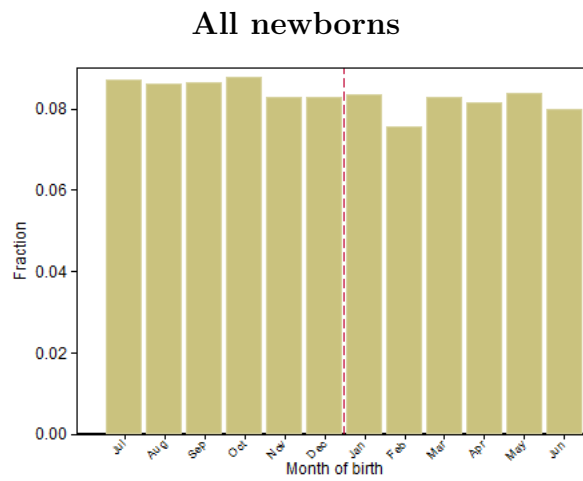

Figure B.2: Birth Characteristics and Month of Birth

Notes: The data come from Spanish birth certificates. The sample includes the universe of Spanish newborns (first five figures), Spanish babies born from mothers without college education (four figures in the middle) or from college educated mothers (last four figures) in the period 2007-2014 (except for July 2010-June 2011). The figures plot, by month of birth, the percentage of babies born from mothers with a college education, from Spanish mothers, from mothers living in a couple, and the average age of the mothers of the newborns or the average number of children of their mothers. Means are represented by dots and 95% confidence intervals are in gray.

Figure B.3: Births by Month of Birth

Newborns of highly educated mothers

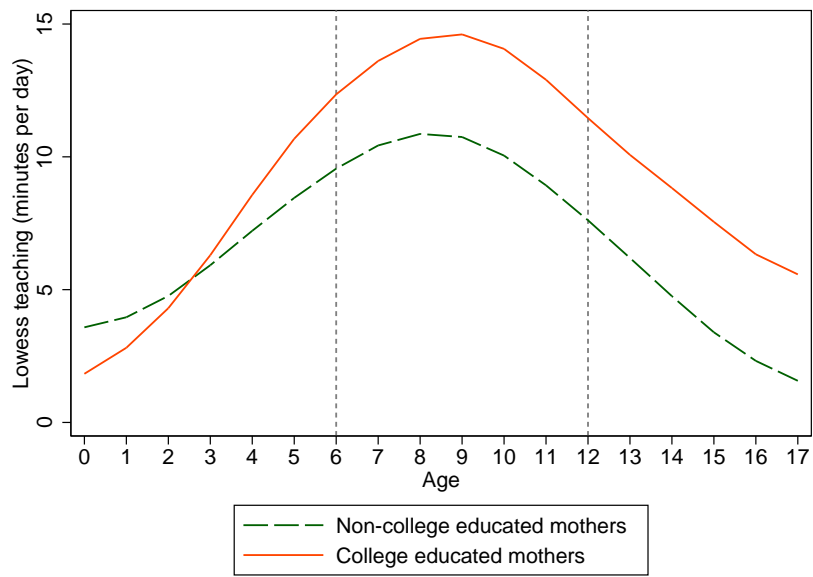

Newborns of poorly educated mothers

Notes: The data come from Spanish birth certificates. The sample includes the universe of Spanish newborns (first figure), Spanish babies born from college educated mothers (second figure) or from mothers without college education (last figure) in the period 2007-2014 (except for July 2010-June 2011). The figures plot, by month of birth, the percentage of births.

Figure B.4: Parental Time Investments by SES and Age: Teaching

Notes: Data from the the Spanish Time Use Survey 2003 and 2009. The sample consists of children aged 0 to 17 born in Spain. The figure plots, by age of the children and socioeconomic status, the minutes parents spent daily with their children doing activities related to teaching.

Table B.1: Parental Education/Socioeconomic Status

	(1)	(2)	(3)	(4)
	College mother	College mother	College mother	Index of SES
	Birth Certificates	STUS	EGD	PISA
Young (December - January) (SE)	0.00962*** (0.00191)	-0.0211 (0.0205)	0.0147 (0.0152)	-0.0104 (0.0183)
Observations	378,624	2,196	3,583	12,311

*Notes:* Column 1 uses data from the Spanish Time Use Survey 2003 and 2009. The sample is of children aged 0 to 17 born in December or January in Spain. Column 2 uses data from the the General Diagnostic Assessment survey 2009. The sample includes Spanish students enrolled in 4th grade. Column 3 uses data from Spanish students aged 15 assessed in PISA 2003, 2006, 2009 and 2012. “Young” is an indicator variable that equals one if the student was born in December and zero if she was born in January. All the reported models include a vector of dummies for birth cohort. Robust standard errors are in parentheses. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1

Table B.2: Birth Characteristics: Children born in January vs December by SES

	Children of non-college mothers			Children of college educated mothers		
	December	December vs. January		December	December vs. January	
	Mean	Difference of means	SE	Mean	Difference of means	SE
Low-weight (<2500 grams)	0.0898	-0.001	(0.001)	0.0776	0.001	(0.001)
Premature	0.0823	0.000	(0.001)	0.0734	0.004**	(0.001)
C-section	0.24	0.000	(0.002)	0.252	0.003	(0.002)
Observations	239,348			139,276		

*Notes:* Data from Spanish birth certificates, period 2007-2014 (except December 2010 and January 2011). The sample includes Spanish individuals born in December and January. First 3 columns show the results for the sample of babies of mothers without college education and the last 3 columns for the sample of babies born from mothers with a college education. Standard errors are in parentheses. \*\*\* p<0.01, \*\* p<0.05, \* p<0.1.

Table B.3: Parental Time investment: Individuals Born in Adjacent Months

	(1)	(2)	(3)
	Teaching	Read and Play	Other childcare
Youngest	-0.145 (1.155)	0.798 (2.466)	-3.135 (6.007)
College mother	1.103 (1.511)	13.55*** (3.560)	35.93*** (8.641)
Youngest X College mother	5.052** (2.560)	-1.554 (4.670)	-1.151 (11.22)
Girl	0.466 (1.067)	-1.957 (2.175)	-7.622 (4.990)
Mean	7.55	22.64	85.74
$\beta_1 + \beta_3$	4.91	-0.76	-4.29
p-value: $\beta_1 + \beta_3 = 0$	0.03	0.85	0.65
Observations	2,196	2,196	2,196

*Notes:* Data from the Spanish Time Use Survey 2003 and 2009. The sample consists of children aged 0 to 17 born in December or January in Spain. The outcome variables indicate the minutes parents spent daily with their children doing different activities: ones related to teaching (Column 1), reading and playing (Column 2), and other childcare activities (Column 3). “Young” ( $\beta_1$ ) is an indicator variable that equals one if the student was born in December and equals zero if she was born in January. The variable “College mother” takes value 1 if the mother of the student has more than secondary education and zero otherwise. Young X College mother ( $\beta_3$ ) is an indicator variable of the interaction between “Young” and “College mother”. All the reported models include a vector of dummies for birth cohort, and day of week and quarter of birth. In this sample, individuals born in the same birth cohort are those born in adjacent months. Standard errors are clustered at the household level. \*\*\*  $p < 0.01$ , \*\*  $p < 0.05$ , \*  $p < 0.1$
